# Blood Pressure Distribution in Indian Children 

Manu Raj, Karimassery Ramaiyer Sundaram*, Mary Paul and Raman Krishna Kumar<br>From the Departments of Pediatric Cardiology and *Biostatistics, Amrita Institute of Medical Sciences and Research Centre, Kochi, India.<br>Correspondence to: Dr Manu Raj, Clinical Associate Professor (Pediatrics), Division of Pediatric Cardiology, Amrita Institute of Medical Sciences and Research Centre, Kochi, Kerala, drmanuraj@gmail.com<br>Received: February 25, 2009; Initial review: April 15, 2009; Accepted: May 21, 2009.

Objective: To determine blood pressure distribution in schoolchildren and to derive population specific reference values appropriate for age, gender and height status.
Design: Cross sectional observational study.
Setting: Schools in Ernakulam district, Kerala, India, during 2005-06.
Methods: Stratified random cluster sampling method was used to select the children. Blood pressure and anthropometric data were collected from 20,263 students of 5-16 years age. Three readings of blood pressures of each child were taken by mercury sphygmomanometer and mean was taken for analysis. Blood pressure percentiles in relation to gender, age and height were estimated from a non-overweight population of 18,931 children using polynomial regression models.

Results: Children from study population have higher diastolic pressures for both sexes than international standard across all age groups. For systolic blood pressure, girls showed higher values than the international standard while for boys, the difference appears to be minimal.
Conclusions: Blood pressure distribution in children from our study population demonstrates a different pattern in comparison to existing international reference. Higher blood pressure values in the study population are of considerable public health significance.
Key words: Adolescents, Blood pressure, India, Obesity, Overweight.

Published online: 2009 September. PII:S097475590900123-1

Hypertension in children is an emerging public health issue attracting the attention of medical professionals worldwide. Hypertension in children exhibits strong correlations with various factors, among which bodyweight assumes considerable significance(1-4). Excess weight resulting in hypertension in children deserves immediate attention even in large developing economies like India, China and Brazil(2,5,6). Data from diverse populations shows that the tracking of blood pressure from childhood into adulthood is very strong(7). In addition to aggravating cardiovascular morbidity and mortality burden, hypertension contributes significantly to other chronic diseases such as stroke and end-stage organ damage $(8,9)$. Throughout adulthood, blood pressure is strongly and directly related to vascular as well as overall mortality(10).

The existing reference values for blood pressure in children were derived from a multiethnic pediatric population from USA(11). The application of this international reference to other populations that differ in various demographic factors, may not be valid. The aim of this study was to plot blood pressure distribution in schoolchildren and to derive population specific reference values appropriate for age, gender and height status.

## Methods

A contiguous area with a population of approximately 1.37 million was selected from Ernakulam district, in central Kerala, India. Sampling was done by stratified random cluster sampling method. Schools in the area were stratified
into 5 groups according to the strength of children and a representative sample of 46 schools with a cumulative population of 25,228 children was randomly chosen. Blood pressure (BP) and anthropometric data (height and weight) were collected from 20,263 students of 5-16 years age during the period 2005-06. Children with body mass index (BMI) more than or equal to 85th percentile of reference data were considered overweight(12). The reference data used to identify the cut offs were taken from CDC 2000 data set for BMI(13). A total of 18,931 non-overweight children were selected from the total sample and used for deriving blood pressure nomograms. Blood pressure was measured using mercury sphygmomanometer. Standard methodology, as recommended by the Fourth Report on the diagnosis, evaluation and treatment of high blood pressure in children and adolescents, was used to measure blood pressure(11). Three readings of blood pressures of each child were taken maintaining an interval of 2 minutes between the readings. Mean of the three readings was reported. Weight and height of each child were recorded using standard methods. The detailed design and methodology is available in our previous publication(2).

## Statistical analysis

Polynomial regression models were considered to estimate blood pressure percentiles in relation to sex, age and height. The same model was adopted previously in computing blood pressure percentiles(11). The model used was a fourth degree polynomial model to predict adjusted blood pressure as a function of age and height Z score for both genders separately. The formulae used for expected BP is given in Annexure I. This expected BP corresponds to mean BP of that particular age and height $Z$ score (Zht) of the specified gender. Using this mean BP and the standard deviation derived from our sample, we derived appropriate values for other BP percentiles. The advantage of using polynomial regression model is that although the distribution of height varies greatly with age, the distribution of Zht does not, thus allowing one to estimate blood pressure percentiles as a function of age and height with a relatively simple polynomial model across a wide age range(14).

## Results

The descriptive data of the school survey is presented in Table I. The mean systolic blood pressure was similar in boys and girls up to the age of 8 years after which girls demonstrated higher values compared to boys till the age of 15 years. At the age of 16 years, boys demonstrated slightly higher values than girls. The mean diastolic blood pressure demonstrated a relative increase in girls by 9 years of age, which stayed till the age of 16 years. The relative increase in systolic blood pressure in girls compared to boys peaked during 11 to 13 years of age. In case of diastolic blood pressure, the relative increase peaked during 12 to 15 years of age.

The regression coefficients from polynomial regression model were derived for both genders separately. The intercept ( $\alpha$ ) for systolic BP was 100.63 in boys and 102.87 in girls. The corresponding values for diastolic BP was 66.25 and 67.35 respectively. The regression, co-efficients for various powers of age $\left(\beta_{1}, \beta_{2}, \beta_{3}\right.$ and $\left.\beta_{4}\right)$ in case of systolic blood pressure for boys were $1.36,0.17,0.02$ and -0.0036 , respectively. The corresponding figures for girls were 2.66, 0.07, -0.03 and -0.0009. The values ( $\beta_{1}, \beta_{2}, \beta_{3}$ and $\beta_{4}$ ) of diastolic blood pressure for boys were 1.21, $-0.08,-0.00013$ and 0.0019 , respectively. The corresponding values for girls were $1.89,-0.06,-0.02$ and 0.001 , respectively. The regression co-efficients for various powers of height z score $\left(\gamma_{1}, \gamma_{2}, \gamma_{3}\right.$ and $\gamma_{4}$ ) in case of systolic blood pressure for boys were 2.30, 0.02, -0.028 and -0.0098 , respectively. The corresponding figures for girls were 1.36, $-0.16,0.015$ and 0.016 , respectively. The values $\left(\gamma_{1}, \gamma_{2}, \gamma_{3}\right.$ and $\left.\gamma_{4}\right)$ of diastolic blood pressure for boys were $1.18,-0.13,0.017$ and 0.012 , respectively. The corresponding values for girls were $0.89,-0.11,0.007$ and 0.012 , respectively. The standard deviation ( $\sigma$ ) for systolic BP was 11.08 in boys and 11.6 in girls, and for diastolic BP was 9.07 in boys and 9.0 in girls.

The height percentiles for both genders from the study population were tabulated separately (Table II). Blood pressure percentile tables were constructed for total sample population after excluding the overweight children (Tables III and

| 16 | 178 | 155.2 (6.58) | 46.6 (8.92) | 19.33 .28 | 114.7 (10.87) | 74.5 (7.10) |

Figures in parentheses are standard deviations. BMI: Body mass index; SBP: Systolic blood pressure; DBP: Diastolic blood pressure.
IV). This was done with the idea that a nonoverweight population should be used to construct a reference nomogram for blood pressure because it avoids the influence of excess weight on blood pressure distribution. Application of this data for clinical and epidemiological purposes is explained in Appendix A. Comparison of blood pressure distribution pattern of both genders show significant differences which persist in both systolic and diastolic blood pressures.

## DISCUSSION

Studies in the past have demonstrated that age appropriate blood pressure values tend to be more among boys than girls through out childhood and adolescence $(11,15)$. The results of our study appear to be at variance to this finding. In our study, there is a relative increase in mean systolic and diastolic blood pressures in girls by the age of 9 years (Table I). By the age of 16 years, both genders have similar

systolic blood pressure values. By the age of 16 years there appears to be minimal differences in diastolic blood pressure between both genders. Similar data was reported in a study from Jordan(16).

Early signs of a change in gender based blood pressure distribution among adolescents are emerging. Comparison of data sets from US adolescents demonstrated an increasing trend for high blood pressure among adolescent girls in contrast to a decreasing trend for the same in adolescent boys(17). The onset of sexual maturation is associated with increases in systolic and diastolic blood pressures $(18,19)$. The timing of sexual maturity is different for boys and girls with the latter attaining it relatively earlier. This difference could contribute to differences in blood pressure progression during adolescence. The same reason could explain the lack of difference in systolic blood pressure and the comparable values in diastolic blood pressure between the genders by age 16, a time at which majority of the boys too have attained significant sexual maturity.

The blood pressure distribution pattern constructed using data from the present study was compared with an existing international reference(14). There appears to be minimal difference in systolic blood pressure among boys from the two populations. There exists difference among girls in
terms of systolic blood pressure with girls from the present study showing higher values consistently for all age groups (Fig.1). The difference in diastolic blood pressure appears to be more than the difference in systolic blood pressure. The same is consistently demonstrated in a higher magnitude in both gender and in all age groups, with children from the present study exhibiting higher values. In addition, the difference in diastolic blood pressure between the populations appears to be more in girls than boys. Higher values for mean systolic as well as diastolic blood pressures in comparison to US data were demonstrated previously for children from Indian, Jordan and Pakistan(16,20-22). All these studies have shown consistently higher diastolic blood pressures in comparison to US children. The differences in systolic blood pressures were less in magnitude compared to that of diastolic pressures. There appears to be a consistent difference in diastolic blood pressures between the present study and the US data(14), pointing towards a populationbased difference. This difference appears to start even before the age of 5 years and persists into late adolescence. Similar trends in Pakistani and Jordanian children support this observation $(16,22)$.

The validity of the results of this study can be ascertained by the relatively significant correlation for both systolic and diastolic pressures with height

Data constructed from the sample of non-overweight girls ( $N=9892$ ).

## What is Already Known?

- Blood pressure in children shows positive associations with age and height.

## What this Study Adds?

- Blood pressure distribution in Indian children exhibits significant differences in comparison to existing US reference values.
and weight as demonstrated by our previous publication from the same database(2). Anxiety among children subjected to blood pressure measurements in a field setting might have influenced the recordings to certain extent. This limitation was unavoidable considering the design of the study. The study results deserve attention due to the anticipated public health implications they predict. Any demonstrable increase in a known cardiovascular risk factor like blood pressure in large populations could seriously result in amplification of morbidity burden resulting from cardiovascular diseases. The morbidity and mortality pattern from cardiovascular diseases in the coming decades when the current pediatric population reaches adulthood appears to be one of grave concern.

Blood pressure distribution in children from this study exhibits a different pattern in comparison to existing international reference. Higher blood
pressure values for our population in comparison to international reference values could contribute to heightened disease burden resulting from hypertension in future. This study underscores the need for a population specific reference for pediatric blood pressure. The public health implications of higher blood pressure values in Indian children starting from a relatively young age could be potentially serious. Further studies from other parts of India are needed to determine the influence of diverse socioeconomic, cultural and nutritional factors on blood pressure in children.

## Acknowledgments

The authors thank Mr Abish Sudhakar and Ms Smitha Mathew for assistance in data management and statistical analysis.

Contributors: MR conceived, designed and drafted the study. RKK supervised and revised the manuscript for important intellectual content. MP managed the data and

FIg. 1 Comparison of blood pressure between the present sample and US children. ## Appendix A

## Identifying BP percentiles for clinical use

For example, a 14-year old boy with height 166 cms has SBP of 126 mm Hg .

First step is to refer to the height percentile table (Table II) and see which percentile of height the boy has. In this case, the boy has $75^{\text {th }}$ percentile of height.

Then, refer the values in BP percentile table corresponding to the case's sex, age and height percentile. In this case, the $50^{\text {th }}, 90^{\text {th }}, 95^{\text {th }}$ and $99^{\text {th }}$ percentiles of SBP for this 14 -year-old boy whose height is in the $75^{\text {th }}$ percentile are 111, 125, 129 and 136 respectively. The observed SBP value of 126 mm Hg lies above $90^{\text {th }}$ percentile, but below $95^{\text {th }}$ percentile. Hence this child will be classified as having systolic pre-hypertension.

Actual BP percentiles assume clinical significance in diagnosis, classification and treatment targets of hypertension in children. Systolic or diastolic BP $\geq 95^{\text {th }}$ percentile for gender, age and height for 3 or more occasions is defined as hypertension in children. Pre-hypertension is defined as systolic BP or diastolic BP that are $\geq 90^{\text {th }}$ percentile but <95 ${ }^{\text {th }}$ percentile. Stage 1 hypertension refers to BP from 95th percentile to the 99th percentile plus 5 mm Hg . Stage 2 hypertension refers to values above stage 1 hypertension. The $50^{\text {th }}$ percentile of BP is the target attempted when
hypertensive children are subjected to anti hypertensive drug therapy.

Calculating exact BP percentiles using polynomial regression equation

Expected BP $\mu=\alpha+\sum_{\mathrm{j}=1}^{4} \beta_{\mathrm{j}}(\mathrm{y}-10)^{\mathrm{j}}+\sum_{\mathrm{k}=1}^{4} \gamma_{\mathrm{k}}(\mathrm{Zht})^{\mathrm{k}}$
where $y$-age in years, ht- height in cms, $\alpha, \beta_{1} \ldots \beta_{4}$ and $\gamma_{1} \ldots . \gamma_{4}$ are regression co-efficients.

For example, a 14-year old boy with height 166 cms has a height equivalent to $75^{\text {th }}$ percentile. The Z score for $75^{\text {th }}$ percentile $=0.6745$. The parameter Age-10 $=4$ in this case .

His expected SBP $(\mu)$ is,

$$
\begin{aligned}
& \mu=100.63+1.36(4)+0.17\left(4^{2}\right)+0.02\left(4^{3}\right)-0.0036\left(4^{4}\right)+ \\
& 2.30(0.6745)+0.024\left(0.6745^{2}\right)-0.028\left(0.6745^{3}\right)- \\
& 0.0098\left(0.6745^{4}\right)=110.70 \mathrm{mmHg} .
\end{aligned}
$$

Suppose his actual SBP is 126 mmHg ( x ); his SBP Z score then equals
$(x-\mu) / \sigma=(126-110.70) / 11.08=1.3809$.
The corresponding SBP percentile $=\varphi(1.3809) \times 100 \%$ $=91.6$ percentile.
